Hardware-based smart camera for recovering high dynamic range video from multiple exposures

Pierre-Jean Lapray, Barthélémy Heyrman, and Dominique Ginhac* University of Burgundy, Le2i UMR 6306, Dijon 21000, France

Abstract. In many applications such as video surveillance or defect detection, the perception of information related to a scene is limited in areas with strong contrasts. The high dynamic range (HDR) capture technique can deal with these limitations. The proposed method has the advantage of automatically selecting multiple exposure times to make outputs more visible than fixed exposure ones. A real-time hardware implementation of the HDR technique that shows more details both in dark and bright areas of a scene is an important line of research. For this purpose, we built a dedicated smart camera that performs both capturing and HDR video processing from three exposures. What is new in our work is shown through the following points: HDR video capture through multiple exposure control, HDR memory management, HDR frame generation, and representation under a hardware context. Our camera achieves a real-time HDR video output at 60 fps at 1.3 megapixels and demonstrates the efficiency of our technique through an experimental result. Applications of this HDR smart camera include the movie industry, the mass-consumer market, military, automotive industry, and surveillance. © 2014 Society of Photo-Optical Instrumentation Engineers (SPIE) [DOI: 10.1117/1.OE.53.10.102110]

1 Introduction

Standard cameras have a limited dynamic range. In many video and imaging systems, we have saturated zones in the dark and illuminated areas of the captured image. These limitations are due to large variations of the scene radiance, with overexposed and underexposed areas in the single image. The sequential capture of several images with different exposure times can deal with the lack of information in extreme lightning conditions.

According to Mantiuk et al., there are two types of devices that can be used to capture the entire dynamic of a scene: high dynamic range (HDR) sensors and standard sensors. The HDR sensors are, by design, able to capture a wide dynamic range with a single capture. However, these sensors are still under development and are not suitable for embedded and low cost applications. Another technique is to use a standard low dynamic range (LDR) sensor. This technique has several ways to proceed:

- changing the exposure time by multiple captures which is the most common method;
- spatial exposition: capture simple, with a mask in front of the sensor;
- multiple sensors with a shared light beam.

According to Gamal,² the multiple capture technique is the most efficient method, widely used in recent works.^{3–5} The creation an HDR image is done in three steps:

- recover the response curve of the system;
- blend pixels into radiance values;

 perform tone mapping to match the dynamic range of the scene to that of the display device.

This technique is designed to calculate the light intensities of real scenes, where each pixel is stored on a very large dynamic range (up to 32-bit wide and more). It is, therefore, necessary to have a large range of memory to store images and to reconstruct the HDR image.

The three most popular algorithms for HDR reconstruction are those of Debevec and Malik,6 Mitsunaga and Nayar,⁷ and Robertson et al.⁸ A technical paper by Yourganov⁹ compares the first two algorithms implemented in C/C++ in real time on a personal computer (PC). The results of computation time for an image are substantially the same. The Mitsunaga algorithm is based on a flexible parametric model able to calculate the response function without the precise exposure times of the different images to merge. They perform automatic rejection of the image parts with significant effects of vignetting, or temporal variations. Originally, the Debevec method was been developed for photography. However, according to the research conducted by Yourganov,⁹ this method can be easily applied to digital video, both for static and dynamic scenes, if captures are fast enough that light changes between two consecutive frames can be safely ignored. Consequently, such a method is widely used to produce HDR video by capturing frames with alternating bright and dark exposures, as pointed out by Tocci et al. 10

HDR creating is followed by the tone mapping operation.¹¹ It is used to render the HDR data to match the dynamic range of conventional hardware displays. For example, it converts 32- to 8-bit wide pixels ([0, 255]). There are two types of tone mapping operators (TMOs): spatially

^{*}Address all correspondence to: Dominique Ginhac, E-mail: dginhac@u-bourgogne.fr

uniform (global TMO) and spatially nonuniform (local TMO). In our case, several algorithms seem to be implementable in real time due to fast computation capabilities, whether global or local. The following is a list of methods known for their efficiency and simplicity. These methods are ordered from the fastest algorithm to the slowest algorithm implemented in software:

- Durand and Dorsey¹² (fast bilateral filtering for the display of HDR images);
- Duan et al. ¹³ (tone-mapping HDR images by histogram novel adjustment);
- Werman et al. 14 (gradient domain HDR compression);
- Reinhard et al.¹⁵ (photographic tone reproduction for digital images);
- Pattanaik et al. ¹⁶ (time-dependent visual adaptation for fast realistic image display);
- Drago et al.¹⁷ (adaptive logarithmic mapping for displaying high contrast scenes).

Representing the reality as closely as possible is a crucial aspect to be considered for any HDR system. Several publications have concerned the evaluation of tone mapping methods. A study by Akyüz and Reinhard shows that the method by Reinhard et al., photographic tone mapping, gives the best results in terms of the natural appearance in the image. Another study by Drago et al. Preaches the same conclusion. Cadík²¹ shows also results in line with the previous ones since the Reinhard method is one of the best ranked method. There is a surprising aspect in this paper: the global part of the methods of tone mapping is critical for achieving good visual results for real-world scenes.

In this paper, we propose an HDR smart camera based on a parallel hardware architecture dedicated to the production of real-time HDR video content from a set of different exposures. From an end-user point of view, the HDR video must be built and delivered at the full resolution and at the sensor frame rate with no detectable latency from each new capture and the frames previously stored. Moreover, this HDR platform embeds all the necessary algorithms to automatically evaluate the best exposure times for any visual scene in order to provide the best HDR content. What is new in this paper is shown through four steps. First, we capture images from the sensor with three alternating exposure times, selected automatically by our multiple exposure control (MEC). Then, we manage reading and writing operations

in memory in order to have several video streams in parallel, corresponding to the different exposure times. Under a highly parallel context, we blend the three video streams together with a modified version of a standard HDR technique. Finally, a hardware implementation of a global tone mapping technique is performed. We will begin this paper by describing the existing works about the HDR video technique in Sec. 2. Then, in Sec. 3, we will describe our system in detail. Finally, some experiments and results will follow this discussion in Secs. 4 and 5. Concluding remarks are then presented in Sec. 6.

2 Related Work

We detail here the existing hardware architectures. We limit ourselves to recent systems which can operate in real time, whether they are focused exclusively on capture, HDR creating or tone mapping. Table 1 summarizes these methods.

In 2012, Gençtav and Akyüz²⁸ developed a complete system on a graphics processing unit (GPU) platform. The tasks are performed in parallel with a pipelined structure. Generating HDR and the tone mapping are done without knowing the response curve of the camera. They use the algorithm originally proposed by Debevec and Malik⁶ to estimate the radiance values. Regarding the operation of the tone mapping, the Reinhard et al. 15 algorithm has been chosen and implemented. Some results are identical to other methods implemented on a central processing unit (CPU). They reach a frame rate of 65 fps for producing HDR images and 103 fps for performing the tone mapping. However, they do not have time to load textures onto the GPU. The majority of time is spent in sending pixels to the GPU. Radiance computations and weighting have little impact on the speed calculation and the frame rate of the final system.

The most popular complete HDR vision project is based on the Mann et al.²³ system. In 2012, a welding helmet composed of two computer-controlled video cameras was presented. The data received by these cameras are recorded line by line in an external memory. Several first in first out (FIFOs) simultaneously store the pixels and read them line by line. The number of FIFOs depends on the number of images used by the HDR reconstruction module. A look-up table (LUT) containing precomputed values is used to combine multiple exposures. This LUT is inspired by the work of Ali and Mann,²⁹ and the estimation of radiances is done with a comparametric camera response function (CCRF). With this method, they are able to obtain a video with a fixed latency and a controlled time calculation on

Table 1 Summary of the main embedded real-time architectures dedicated to HDR.

a Xilinx Spartan 6, model LX45 field-programmable gate array (FPGA).

Ureña et al.²⁴ published two tone mapping architectures, described both on a GPU and an FPGA. The implementations were done on a portable battery operating circuit. A new generation of tone mapping is presented in this paper. The TMO includes both local and global calculations. Typically, for the overall look, it highlights the areas containing low contrasts, but can also protect areas where the contrast is more well defined. Locally, it reduces the areas that are too bright in order to improve the image details. The overall improvement is based on the brightness histogram adaptation of each channel in the HSV color space. On the other hand, the local enhancement is based on the retina-like technique. To summarize, the Gaussian filters, the weighting and the human visual system consideration are the main advantages of the operator. The FPGA implementation produced a video with a high frame rate, consuming little electric power, while the GPU implementation provides greater precision in the calculation of HDR pixels, but uses a lot of resources.

In 2012, Guthier et al.³⁰ introduced an algorithm with a good HDR quality that can be implemented with the same number of LDR captures. The choice of exposures is optimally performed by selecting the better shutter speeds that will add more useful information to contribute to the final HDR image. The context can be real time by minimizing the number of images. Basically, the exposure times are wisely chosen so that at least one LDR image has a wellexposed pixel at one position (i, j). First, a good approximation of the radiance value E is calculated taking into account the response function of the camera and a contributing function. A useful relationship is made between the radiance histogram vector and the contribution of each image that indicate potential changes in the scene. A stability criterion is also introduced to the sequence which allows each frame to be adjusted until a stable shutter sequence is found. Finally, with this algorithm, capturing time is saved and the number

of LDR exposures are reduced without loss of quality at the end of the computation.

Chiu et al.²⁶ suggest a methodology to develop a tone mapping processor optimized using an ARM system on chip (SOC) platform. Their processor evaluates both the photographic compression method by Reinhard et al.¹⁵ and the gradient compression method by Werman et al.¹⁴ for different applications. The new processor can compress 1024 × 768 HDR images at 60 fps. The core needs 8.1 mm² of physical area with 0.13 m TSMC technology.

Bachoo²⁷ developed a dedicated technical application of exposure fusion (initiated by Van Reeth et al.³¹) to merge a real time 1600×1200 video at 20 fps using three black and white videos. They are able to control the speed of image generation and to have a constant frame rate relative to the defined processing block size. They perform an alternative Goshtasby³² algorithm. The implementation is done on a CPU and GPU. The algorithm is divided into two parts so that the power of the CPU processing and GPU are used wisely. The CPU perform massively sequential operations such as calculating entropy blocks. The GPU is used to merge the blocks together, an operation that can be parallelized to increase the execution speed of the fusing process. The speed can be increased if the video resolution is reduced or if the size of the processing blocks increases. A compromise between calculation speed and quality can be chosen. Nothing is said about the choice of exposure time and no method is proposed to estimate exposures. It is recorded that the use of additional exposures may produce a bottleneck in the fusing process.

3 Dedicated HDR Smart Camera

The dedicated hardware platform is a smart camera built around a Xilinx ML605 board, equipped with a Xilinx Virtex-6 (San Jose, CA) XC6VLX240T [see Fig. 1(a)]. The motherboard includes a 512 MB DDR3 SDRAM memory used to buffer the multiple frames captured by the sensor. Several industry-standard peripheral interfaces

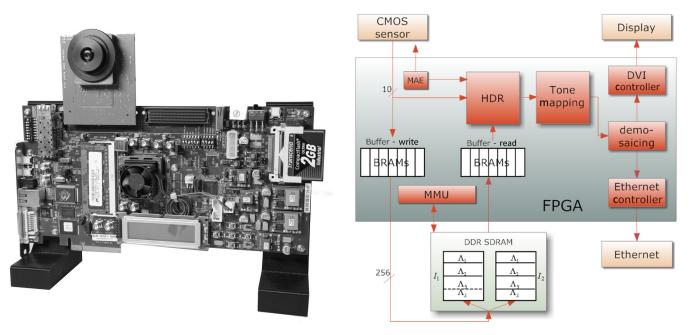

Fig. 1 Overview of our high dynamic range (HDR) smart camera.

are also provided to connect the system to the external world. Among these interfaces, our vision system implements a DVI controller to display the HDR video on an LCD monitor. It also implements an Ethernet controller to store frames on a host computer. A custom-made PCB extension board has been designed and plugged into the FPGA board to support the Ev76c560 image sensor, a 1280×1024 -pixel CMOS sensor from e2v. It offers a 10-bit digital readout speed at 60 fps in full resolution. It also embeds some basic image processing functions such as image histograms and evaluation of the number of low- and high-saturated pixels. Each frame can be delivered with the results of these functions encoded in the video data stream header.

The parallel architecture presented in this paper operates in several stages. At the first stage, an FPGA input interface sequentially receives three pixel streams (produced by the e2v sensor EV76C560), and stores them to a memory as mosaiced color images. No demosaicing is performed at this time. An MEC based on the histogram computation also operates in parallel to select the proper exposure times. It changes the sensor configuration each time an image is captured. The second stage is based on a memory management core which reads the previous frames stored into the SDRAM and delivers them as synchronized parallel video outputs. At the third stage, the different pixel streams are combined into an HDR frame, for which the response curve of the imaging system and the exposure times of the images are known. This stage produces a complete radiance map of the captured scene. Finally, the HDR frame is tone mapped and can be displayed on a standard LCD monitor via a DVI controller. This full process is continuously updated in order to perform a real-time HDR live video at 60 fps with a 1280×1024 pixel resolution. Our real-time constraint is that the availability of new HDR data from the LDR captures must not exceed a fixed latency of 1 ms, guaranteeing that the HDR process is imperceptible to the viewer.

Our camera must be automatically adapted to the illumination level, just as the human eyes are. The best set of exposures has to be evaluated in order to capture the adequate

dynamic range of the scene. But when we perform HDR stitching, traditional autoexposure algorithms fail. We present a similar approach to a previous state-of-the-art algorithm by Gelfand et al., 33 adapted to our real-time hardware requirement. Our sensor is able to send us the complete image histogram. Using the histogram of each image will allow to us have a preview of the total range of brightness that is being recorded. We require that fewer than 10% of the pixels are saturated in white for the short exposure, and require that fewer than 10% of pixels are saturated in dark for the long exposure, as illustrated in Fig. 2.

However, the method developed by Gelfand for the evaluation of the exposure times has been specifically designed for HDR photography on smartphones. Their approach is optimal to capture a single HDR image, but cannot be considered for an HDR video. In our approach, we decide to continuously update the set of exposure times from frame to frame to minimize the number of saturated pixels by instantaneously handling any change of the light conditions. The estimation of the best exposure times is computed from the 64-level histogram automatically provided by the sensor in the data-stream header of each frame. Let us call $\Delta t_{\rm L}$, $\Delta t_{\rm M}$, and $\Delta t_{\rm H}$ the three exposure times related to our scene. Image histograms provided by the sensor are encoded with 64 categories with 16 bits by category. According to the captured images with low exposure I_L and high exposure $I_{\rm H}$ times, we apply these equations

$$Q_{\rm L} = \sum_{h=1}^{h=4} \frac{q(h)}{N} \qquad Q_{\rm H} = \sum_{h=60}^{h=64} \frac{q(h)}{N}, \tag{1}$$

where $Q_{\rm L}$ and $Q_{\rm H}$ are the proportion of pixels on a specific part of the histogram among N pixels that compose an image. q_h is the number of pixels in each bin h. The calculation is done with the first four and the last four categories in the images $I_{\rm H}$ or $I_{\rm L}$. The output pixels are encoded with 10 bits (between 0 and 1023) and four categories correspond to a range of 64 pixel values. Then, we calculate one parameter for both extreme exposure times as

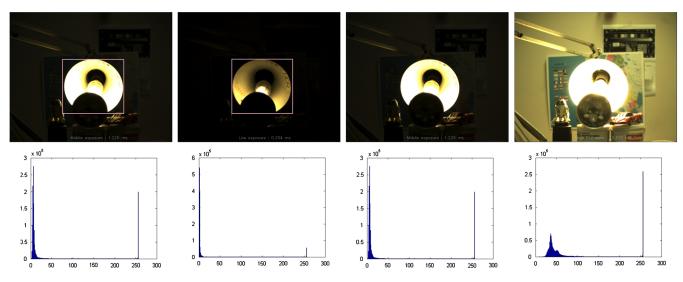

Fig. 2 From left to right, the first image shows 15.3% of pixels saturated at high level for the short exposure before MEC, whereas the second image has only 5.4% of these pixels after MEC. In the same manner, the third image shows 38.3% of pixels saturated in black before MEC and the fourth image only includes 0.2% after MEC.

$$\delta Q_{\rm L/H} = |Q_{\rm L/H} - Q_{\rm L/H,req}|,\tag{2}$$

where $Q_{\rm L/H,req}$ is the required pixel quantity for a specific part of the histogram (10% among N). $\delta Q_{\rm L/H}$ evaluates the number of the current pixels with the desired quantity. Once we have these parameters, the system completes a series of decisions to the next image captures at t+1

$$\Delta t_{L/M/H,t+1} \leftarrow MEC(\Delta t_{L/H,t}),$$
 (3)

$$\Delta t_{\mathrm{L},t+1} = \begin{cases} \Delta t_{\mathrm{L},t} \pm 1x & \text{for } \delta Q_{\mathrm{L}} > \text{thr}_{\mathrm{Lm}} \\ \Delta t_{\mathrm{L},t} \pm 10x & \text{for } \delta Q_{\mathrm{L}} > \text{thr}_{\mathrm{Lp}} \end{cases}, \tag{4}$$

$$\Delta t_{\mathrm{H},t+1} = \begin{cases} \Delta t_{\mathrm{H},t} \pm 1x & \text{for } \delta Q_{\mathrm{H}} > \mathrm{thr}_{\mathrm{Hm}} \\ \Delta t_{\mathrm{H},t} \pm 10x & \text{for } \delta Q_{\mathrm{H}} > \mathrm{thr}_{\mathrm{Hp}} \end{cases}, \tag{5}$$

$$\Delta t_{\mathrm{M},t+1} = \sqrt{\Delta t_{\mathrm{L},t} \Delta t_{\mathrm{H},t}},\tag{6}$$

where $\Delta t_{L/M/H,I}$ are the values of the exposure times of the current images I_L , I_M , and I_H .

To obtain a correct convergence time, the exposure time is automatically adjusted using two different levels of thresholds: one for a small variation of illumination and the other one for a greater range of illumination changes. thr_m (minus) and thr_p (plus) are the two threshold values that correspond to two different levels of action for the adjustment of exposure time. These thresholds will directly affect the transition speed to a stable state. For example, when you have a sudden increase in light in a short space of time, it affects the sensor exposure time according to thr_p. x determines how we change exposures. Here, it corresponds to the sensor time line, $x = 15.72 \mu s$.

4 Implementation

4.1 Specific HDR Memory Management Core

The use of external off-chip memories is judicious for our application that processes large amounts of data and high data rates. For our case, video processing requires two frames of data to be stored. In practice, this storage is implemented using a DDR3 SDRAM chip which is a part of our hardware development platform. It requires fast and efficient direct memory access logic to achieve the HDR video in real time.

The sensor is able to send full-resolution images at 60 fps. Initialization of our specific HDR memory management core is shown in Fig. 3. I_1 and I_2 are first stored in DDR3 memory. The first frame (I_1) is stored row by row with the function $W\Lambda_\lambda I_1$, where λ indexes row number $(1 \le \lambda \le 1024)$. For example, $W\Lambda_1 I_1$ means "writing of the first row Λ_1 of I_1 into memory." Each row write operation is followed by an interrow delay, due to horizontal sensor synchronization. For the second frame I_2 , the image is also stored row by row $(W\Lambda_\lambda I_2)$. This initialization step is required before the generation of the first HDR frame. We cannot avoid waiting for these two first exposures. After this step, the memory management core can start (see Fig. 4).

During the capture of the last frame (I_3) , rows of the two previous frames stored are synchronously read from the memory during interframe $(R\Lambda_{\lambda}I_1, R\Lambda_{\lambda}I_2)$ and buffered into block RAMs (BRAMs) while each new captured row $(W\Lambda_{\lambda}I_3)$ is stored in memory. It is important to notice that the design is a pure-hardware system which is processor-free and must be able to absorb a continuous pixel flow of about 80 megapixels (MP)/s from the sensor (called "Memory In" in Figs. 3 and 4) while reading two other pixel flows corresponding to the two stored images (respectively called "Memory Out 1" and "Memory Out 2" in Fig. 4).

The HDR content is computed with the methods described in Secs. 4.2 and 4.3. The HDR process needs a continuous stream of pixels for three images and then can only be performed while receiving the third frame I_3 . Then, the process can iterate throughout the capture of the fourth frame (low exposure I_4) and the readout of the second and third frames (I_5 and I_6). Finally, our memory management system is able to deliver two parallel pixel streams that have been acquired and stored into the memory and a third pixel stream directly from the sensor. With this technique, each HDR pixel only requires three memory accesses (one write and two read operations during one row interval), saving many memory access operations. The main advantages of such a technique are (1) to store only two images in memory and (2) to avoid waiting for the three images to compute an HDR image. A latency corresponding to 136 clock rising-edges (i.e., 1.2 μ s for a 114 MHz system clock) is required by the system to create the HDR tone mapped data (gray part of HDR output in Fig. 4) from the three captured lines. Then it delivers an HDR video

Fig. 3 Memory management core initialization. The sensor sends sequentially low (I_1) and middle (I_2) exposure times. Writing operations into memory of each rows Λ indexed by λ of the first two frames.

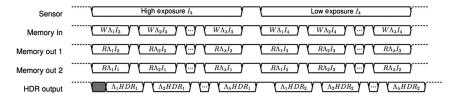

Fig. 4 Memory management core. Performing three parallel streaming videos with low (I_1) , middle (I_2) , and high (I_3) exposure times. The delayed HDR row output is shown after HDR and tone mapping computations (related to Secs. 4.2 and 4.3).

stream at 60 fps which is directly updated at each time the sensor sends an image.

4.2 HDR Creating

The evaluation of the response curve of the system g only requires the evaluation of a finite number of values between Z_{\min} and Z_{\max} (typically 1024 values for a 10-bit precision sensor), as depicted in the paper of Debevec and Malik. This evaluation is not required if the camera has a linear response. However, for the major parts of image sensors, including the sensor used in our hardware platform, the response is not linear. The most significant nonlinearity in the response curve is around the saturation points (i.e., very dark pixels and very bright pixels), where any dark (respectively, bright) pixel with a radiance below (respectively, above) a certain level is mapped to the same minimum (respectively, maximum) image value. The evaluation of the response curve has not been implemented on the hardware platform because it needs to be computed only once for a given sensor. Therefore, these values are preliminarily evaluated by a dedicated PC software (MATLAB code provided with the Debevec paper) from a sequence of representative images, and then stored into an LUT (1024-word memory) on the FPGA for further reuse to convert pixel values. For recovering the HDR luminance value E_{ij} of a particular pixel, all the available exposures of this pixel are combined using the following equation:

$$\ln E_{ij} = \frac{\sum_{p=1}^{p=3} \omega(Z_{p,ij}) [g(Z_{p,ij}) - \ln \Delta t_p]}{\sum_{p=1}^{p=3} \omega(Z_{p,ij})},$$
(7)

where p indexes the image number, i and j index the pixel positions, Δt is the exposure time, and $\omega(z)$ is a weighting function giving a higher weight to values closer to the middle of the function

$$\omega(z) = \begin{cases} z - Z_{\min} & \text{for } z \le \frac{1}{2} (Z_{\min} + Z_{\max}) \\ Z_{\max} - z & \text{for } z > \frac{1}{2} (Z_{\min} + Z_{\max}) \end{cases}, \tag{8}$$

where Z_{\min} and Z_{\max} values depend on the sensor output dynamic (typically 1024 values for a 10-bit precision sensor).

Considering $Z_{1,ij}$, $Z_{2,ij}$, and $Z_{3,ij}$ as $Z_{L,ij}$, $Z_{M,ij}$, and $Z_{H,ij}$, the overall scheme is visible in a pipeline architecture in Fig. 5. Computation of luminance values requires the use of 32-bit arithmetic operators (subtractors, multipliers, etc.) and a transition from 10-bit to IEEE754 32-bit wide (called "Fixed-to-Float" in Fig. 5). LUTs are used to store response curve g and make the transition from exposure time values $\Delta t_{\mathrm{L/M/H}}$ to a neperian logarithm field. These LUTs are used to avoid too much large hardware utilization. Floating-point operators with a large data bus have been chosen according to a detailed study of the arithmetic operators on the FPGA,³⁴ focusing on the estimation surface and time for floating and fixed operators. They note that the surface increases exponentially with the accuracy (number of bits of representation). In addition, output delays increase linearly with precision. In view of these results, it was particularly interesting to consider implementations provided by Xilinx, including floating-point operators. The choice of using floating algorithms became spontaneous given the huge dynamic computations necessary for radiances. Moreover, as indicated in Table 2, the floating architecture does not significantly consume more resources than the fixed-point architecture.

4.3 Tone Mapping

Once the radiance map is recovered, image pixels have to be mapped to the display range of a selected material. In our case, the displayable range is 2⁸ values. Reinhard et al. 15 require one global computation: the log average luminance found in the image, calculated as

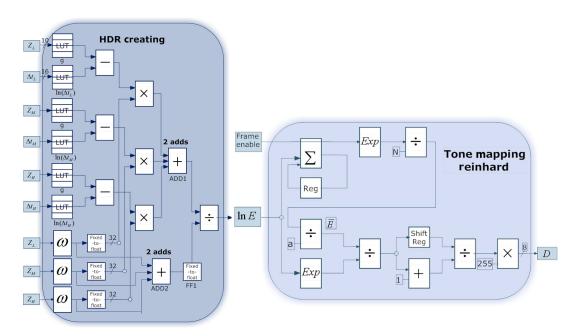

Fig. 5 HDR creating and tone mapping hardware pipeline using three different pixel streams. Frame enable is active when a new HDR frame is coming. It is important to note that we use IEEE754 32-bit floating-point arithmetic operators.

Table 2 Resource comparison of fixed and floating point arithmetic operators on Virtex-6.

	Fixed poir	Floating point		
Operator	LUTs	DSPs	LUTs	DSPs
Add/sub	75	0	477	0
	0	1	287	2
Multiplication	696	0	659	0
	132	1	107	3
Divider 1 cycle	1377 (Radix-2)	0	780	0
Divider 25 cycles	_	_	187	0
Root mean square 1 cycle	1550	0	533	1
Root mean square 25 cycles	_	_	170	1

$$\bar{E}_{ij} = \exp\left(\frac{1}{N}\sum_{i,j}\ln E_{ij}\right),\tag{9}$$

where E_{ij} is the scene radiance for pixel (i, j), and N is the total number of pixels in the image. Then we want to map the middle-gray scene luminance to the middle-gray of the displayable image. For the photographic tone reproduction operator, one approach is to scale the input data such that the log average luminance is mapped to the estimated key of the scene

$$D_{ij} = 255 \cdot \frac{a \frac{E_{ij}}{\bar{E}_{ij}}}{1 + a \frac{E_{ij}}{\bar{E}_{ij}}} = 255 \cdot \frac{1}{1 + \frac{\bar{E}_{ij}}{a \cdot E_{ij}}},$$
 (10)

where a is a scaling constant appropriate to the illumination range of the image scene. We empirically chose 0.18 in our case.

5 Results and Discussion

5.1 Hardware Implementation

Our work has been implemented on a Virtex-6 platform. We show the hardware implementation results in Table 3. Usually, FPGA-based image processing requires many specific devices such as SRAM memory, multiport memory, video direct memory access, dedicated processors, and consequently, consumes many DSP blocks. This is not the case for our implementation. It requires a relatively low hardware complexity since the number of occupied slices is 6692 (about 17% of the device) and the number of LUTs is 16,880 (i.e., 11% of the device). These results highlight several interesting points. First of all, since the hardware utilization is limited with the Virtex-6 platform, it gives us the opportunity to implement the full HDR pipeline onto a less powerful FPGA like a Xilinx Spartan-6 LX45, providing a lower cost HDR smart camera. Second, our technique can be extended to more complex processing architectures. Among them, we can cite more complex TMOs and, specifically, local operators, known to give an enhanced visual

Table 3 Summary of hardware implementation results on the Virtex-6 platform.

Metric	Utilization/availability	%
Estimated supply power	6.039 W	
Maximum frequency	126.733 MHz	
Number of occupied slices	6692 out of 37,680	17%
LUTs	16,880 out of 150,720	11%
Registers	20,192 out of 301,440	6%
Number of bonded IOBs	196 out of 600	32%
36 K BRAMs	17	4%

performance. Finally, we can also consider implementing HDR pipelines using more than three LDR exposures in order to capture more details in the scene.

Two series of captures of digital still images from the different video LDR streams are shown in Fig. 6. For the two sets, you can see, from left to right, the contributions from the different LDR frames (low, medium, and high exposures) and the HDR image. As an example, for the first series, we can distinguish the word "HDR" inside the lamp (high brightness), and the word "HDR" inside the tube (low brightness). A video of the scene with the lamp is also available on Fig. 7. In the first frames, the video shows the different LDR flows (low, medium, and high exposures from left to right) that have been put together on the same shot. The video ends with the resulting HDR video.

Our design has a horizontal blanking period of 307 pixels, and a vertical blanking period of 20 rows. The entire design contains hardware and algorithm latencies. The efficient latency at the end of each row is 127 extra clock ticks (1.11 µs for a clock pixel of 114 MHz). This constant latency appears but does not alter the frame rate. Indeed, we use the horizontal blanking periods delivered by our sensor to compensate the latency. With a video frame rate of 60 fps, our system is able to process $60 \times (1280 + 307) \times$ (1024 + 20) = 99.40 MP/s. The hardware system has a maximum operating frequency of 126.733 MHz. Since the video input and video output interfaces are running at 114 MHz, is it acceptable to have a lower system clock? The answer is yes because, during active video, we will support the back-pressure on the slower clock using the BRAMs. During blanking periods, the BRAMs will empty and the interface will catch up. Finally, our architecture embeds all the algorithmic operators to produce a single tone-mapped output pixel in real time.

5.2 Visual Quality

HDR image quality metrics require the availability of a reference image with which the images using the different TMOs are to be compared. In this paper, the reference image is Paul Debevec's HDR photo of Stanford Memorial Church, used historically in the seminal works on HDR.⁶ This reference image has been built from the original LDR exposures series of the church, and tone-mapped with the adaptive logarithmic mapping of Drago et al.¹⁷ This technique is

Fig. 6 Results of the complete system. Our multiple exposure control can select the three proper exposures, and the specific memory management core permits us to display the three bracketed images. The HDR image is in the right of each image set.

Fig. 7 Output video (MPEG, 3 MB) [URL: http://dx.doi.org/10.1117/1.OE.53.10.102110.1].

described as the most natural method and also the most detailed method for dark regions.³⁵ A specific test software implementing the different TMOs has been developed in MATLAB and used to precisely evaluate the quality of each tone mapper. Since our hardware implementation relies on three exposures, we used the three LDR images of Fig. 8

in order to compare the different methods. The exposure time for these three images are, respectively, 32 s, 1 s, and 31 ms from left to right.

Image quality metrics can be divided into two main categories. The first category is difference based metrics. Among them, the most widely used quality metrics are mean square error (MSE) and peak signal-to-noise ratio (PSNR) because they are simple mathematical measures evaluating the distortion between the image and the reference. However, they are not well matched to perceived visual quality because they do not take the characteristics of the human visual system into account.³⁶ For the performance evaluation of different TMOs, subjective criteria as the human perception is of crucial importance. So, the second category of quality metrics includes only human visual system based metrics. Among them, Universal Quality Index (UQI³⁷) and Structural Similarity (SSIM³⁶) are used for measuring the perceptual similarity of the tone mapped images. UQI is an image quality index that models the image distortion as a combination of three factors: loss of correlation, luminance distortion, and contrast distortion. In UOI, local statistics are computed to estimate a similarity between all corresponding 8 x 8 blocks across input and reference images. The SSIM index is a generalized form of

Fig. 8 The three low dynamic range images used for quality comparison.

Table 4 Comparison metrics derived from our test software for TMOs algorithms applied to an HDR image constructed from three exposures.

ТМО	UQI	SSIM	MSE	NRMSE	Time (s)
This work [Reinhard et al. (global) ¹⁵]	0.89	0.8	79.86	0.32	5.52
Drago et al. ¹⁷	0.54	0.58	20.91	0.1	5.43
Reinhard et al. (local) ¹⁵	0.93	0.81	174.13	0.68	10.45
Schlick et al. ⁴⁰	0.43	0.56	5.53	0.03	5.50
Pattanaik et al. ¹⁶	0.14	0.29	4.09	0.02	5.59

UQI for measuring the similarity between two images. In the SSIM metric, the image structure is represented by statistical measures (mean and variance), and image quality is measured based on the similarity between the structure of the reference and the test image. Therefore, a high-quality test image has a structure that closely matches the structure of the reference. SSIM is based on a specific measure of spatial correlation between the structure of the images to quantify the degradation of the image structure.³⁸ This metric imitates the human perception of image structure and returns results that are more consistent with the human visual system than those of MSE and PSNR.

Table 4 summarizes the comparison results in terms of image quality of the tone mapped images produced by our technique and by other methods using the above mentioned metrics: UQI, SSIM, MSE, normalized root mean square error (NRMSE), and computation times. In terms of visual quality, our method outclasses all the other methods (Drago et al., Schlick et al., and Pattanaik et al.) with the highest values both for UQI (0.89) and SSIM (0.8), while having similar computation times. Moreover, our method gives a better performance than the high-complexity local method proposed by Reinhard et al. because we obtain an identical performance in terms of UQI and SSIM, but with 50% less processing time. In terms of MSE and NRMSE, the performance evaluation gives opposite results, with a lower performance compared to Drago et al., Schlick et al., and Pattanaik et al., but higher than Reinhard et al. Such results are in line with those obtained by Ponomarenko et al.³⁹ showing that the widely used metrics such as MSE have very low correlation with human perception.

The major and well known problem of the HDR technique by multiple exposures is the difficulty in removing unwanted motion artifacts occurring during the reconstruction of the radiance map. Ghost detection and ghost removal are under research to provide better HDR video quality. The current system is limited by the bracketing spatiotemporal dissimilarities that may occur during image capture. These artifacts can be global or local. The global ghost occurs when LDRs are misaligned during camera movement when shooting with a hand-held camera, for example. The other type of ghost comes from movement of an object in the scene during acquisition. This anomaly may render HDR imaging inoperative in some application areas. In our case, we have not implemented motion correction, but due to the high frame rate, the effect is only noticeable with highly dynamic motions.

6 Conclusion

An HDR camera with a complete system from capture to display has been designed for rendering HDR content at full resolution and frame rate. We show that HDR video with the original HDR technique at a high frame rate is feasible. Some effort has to be made toward standardization, compression, and sharing HDR data. The multiple exposure technique can cause problems due to scene motion, but our application is not affected by this to any significant amount, as such extremely rapid scene motion does not happen in our captured scenes. This is partly due to the fact that we used a dedicated memory management core which delivers multiple videos in parallel at 60 fps. For extremely rapid scene motion, our HDR system may be prone to ghosting artifacts. Therefore, we plan to study and implement onto the FPGA dedicated ghost detection techniques in order to provide a real-time ghost-free HDR live video.

Pierre-Jean Lapray received his master's degree in embedded electronics engineering from the Burgundy University. He is currently working towards a PhD in the Electronical Department of LE2I (Laboratory of Electronic, Computing and Imaging Sciences) at the University of Burgundy. His research interests include image enhancement techniques, embedded systems and real-time applications.

Barthélémy Heyrman received his PhD in electronics and image processing from Burgundy University, France, in 2005. He is currently an associate professor at the University of Burgundy, France, and a member of LE2I UMR CNRS 6306 (Laboratory of Electronic, Computing and Imaging Sciences). His main research topics are system-on-chip smart cameras and embedded image-processing chips.

Dominique Ginhac received his master's degree in engineering (1995) followed by a PhD in computer vision (1999) from Blaise Pascal University (France). He then joined the University of Burgundy as an assistant professor (2000) and became a member of Le2i UMR CNRS 6306 (Laboratory of Electronic, Computing and Imaging Sciences). In 2009, he was promoted to professor. He is currently deputy director of the Le2i laboratory. His research activities were first in the field of rapid prototyping of real-time image processing on dedicated parallel architectures. More recently, he has developed an expertise in the field of image acquisition, hardware design of smart vision system, and implementation of real-time image-processing applications.
